Abstract: The growing human population will require a significant increase in agricultural production. Changes in the climatic and environmental conditions under which our crops are grown has resulted in the appearance of new diseases, while genetic changes within the pathogen have resulted in the loss of previously effective sources of resistance. We need to intensify the identification and characterisation of new sources of resistance, and use our knowledge of plant-pathogen interactions to develop novel approaches to achieve effective resistance within our crops. Advanced genetic and statistical methods of analysis enable global screens of genetic diversity to be undertaken, identifying new resistance genes, while studies of plant-pathogen interactions are uncovering the mechanisms by which the resistance is achieved. Informed deployment of major, race-specific and partial, race-nonspecific resistance, either by conventional breeding or transgenic approaches, will enable us to produce crop varieties with effective resistance, without impacting on other agronomic importance crop traits.

Dear Rhiannon Macrae

Attached is the invited review, title "Plant-pathogen interactions: disease resistance in modern agriculture", for the Trends in Genetics special issue "Genetic Pastures".

Authors: Dr Lesley A Boyd, Dr Chris Ridout, Dr Donal O'Sullivan, Prof Jan Leach and Dr Hei Leung.

Regards

Lesley Boyd

Abstract

1
2 The growing human population will require a significant increase in agricultural
3 production. Changes in the climatic and environmental conditions under which our
4 crops are grown has resulted in the appearance of new diseases, while genetic
5 changes within the pathogen have resulted in the loss of previously effective sources
6 of resistance. We need to intensify the identification and characterisation of new
7 sources of resistance, and use our knowledge of plant-pathogen interactions to
8 develop novel approaches to achieve effective resistance within our crops.
9 Advanced genetic and statistical methods of analysis enable global screens of
10 genetic diversity to be undertaken, identifying new resistance genes, while studies of
11 plant-pathogen interactions are uncovering the mechanisms by which the resistance
12 is achieved. Informed deployment of major, race-specific and partial, race-
13 nonspecific resistance, either by conventional breeding or transgenic approaches,
14 will enable us to produce crop varieties with effective resistance, without impacting
15 on other agronomic importance crop traits.

The human population has more than doubled in the past 50 years and is projected to increase to over 9 billion by 2050 [1]. The issues underlying global food security are among the most pressing issues in international politics. Although many factors contribute to the disproportionate distribution of food around the world, it is clear that food security will require an increase in sustainable agricultural production, and particularly the production of the cereals wheat, rice and maize [<http://faostat.fao.org>]. Biotic stresses, including biotrophic and necrotrophic fungal, bacterial and viral pathogens, are a major constraint to production. For wheat, significant changes in the pathogen threat have occurred in recent years. For example, in 1999 in eastern Africa, a new race of *Puccinia graminis*, the causal agent of stem rust, overcame the race-specific resistance gene *Sr31* present in 70% of wheat cultivars [2]. In 2000, a new and more aggressive race of *P. striiformis*, the stripe rust pathogen, appeared in the USA causing wide-spread epidemics across the Midwest [3]. In Brazil a new field disease of wheat was discovered in 1986 caused by the rice blast fungus *Magnaporthe oryzae* [4].

These examples highlight the urgent need to better understand crop-pathogen interactions and how this knowledge can be applied in agricultural strategies. As phrased by Prof. Robert McIntosh and Zakkie Pretorius, “Wheat breeding for disease control is not complete unless we encompass all aspects of global pathogen variability and epidemiology, resistance discovery and genetic characterization, germplasm development (pre-breeding), and capture of resistance in competitive high-yielding, high-quality varieties with sufficient adaptability for adoption in agriculture.” [5]. Here we discuss scientific advances in our understanding of the

1 genetics of plant-pathogen interactions and developments in methods of
2 identification and assessment of genetic variability for disease resistance, with an
3 eye towards developing approaches to achieve sustainable disease resistance in our
4 crops.

10 Our current understanding of plant-pathogen interactions and resistance

11
12 The interactions between plant and pathogen involve two-way communication. Not
13 only must the plant be able to recognise and defend itself against a potential
14 pathogen landing on its surface, but the pathogen must be able to manipulate the
15 plant's biology to create a suitable environment for its growth and reproduction. Both
16 plant and pathogen have evolved a suite of genes which enable this communication.
17 Currently the active defence responses of the plant are considered to operate at two
18 levels [6]. The first line of active plant defence involves the recognition of pathogen
19 (or 'microbe')-associated molecular patterns, PAMPs (or 'MAMPs'), which trigger
20 general plant defence responses referred to as PAMP-Triggered Immunity (PTI). The
21 pathogen is able to suppress the different components of PTI by "effector" proteins
22 delivered into the plant. The second line of plant defence involves the recognition of
23 specific effectors (now referred to as Avirulence (Avr) proteins) by resistance (R-)
24 genes within the plant, triggering what is often perceived as a stronger resistance
25 response and referred to as Effector-Triggered Immunity (ETI). This R/Avr-gene
26 recognition has been termed gene-for-gene resistance [7]. For a current review of R-
27 gene application and future application in crop disease management see [8].

PTI and crop resistance

1
2 PAMPs are essential pathogen molecules that cannot be deleted or mutated and are
3
4 highly conserved amongst a diverse range of microbial species. The best
5
6 characterised plant recognised PAMPs are flg22, a subunit of the most conserved
7
8 region of the bacterial mobility protein flagellin [9] and elf18, an epitope within EF-Tu,
9
10 a bacterial elongation factor and the most abundant bacterial protein [10]. Chitin, a
11
12 constituent of fungal and insect cell walls is the best-studied fungal PAMP [11]. Other
13
14 PAMPs include fungal xylanase, oomycete heptoglucans and bacterial
15
16 lipopolysaccharides [12].

22
23

24 Recognition of PAMPs by plant Pattern Recognition Receptors (PRRs) initiates PTI,
25
26 a series of defence reactions sufficient to repel most invading microbes. In recent
27
28 years there have been significant advances in our understanding of PAMP-PRR
29
30 interactions and the subsequent signalling events [12]. The bacterial PAMPs flg22
31
32 and elf18 are recognised by the *Arabidopsis* PRRs Flagellin Sensing 2 (FLS2) [13]
33
34 and EF-Tu Receptor (EFR) [14], both of which are leucine-rich repeat receptor-like
35
36 kinases (LRR-RLKs). Chitin is recognized in rice by the LysM domain-containing
37
38 receptor-like protein (RLP) Chitin Elicitor Binding Protein (CEBiP) [15] and requires
39
40 the RLK Chitin Elicitor Receptor Kinase 1 (CERK1) to trigger PTI [16]. PRRs have
41
42 also been found that can detect the peptides or cell wall fragments released during
43
44 infection or wounding, referred to as Damage-Associated Molecular Patterns
45
46 (DAMPs) [17].

crops (Figure 1). One of the earliest cellular responses following PAMP elicitation is the oxidative burst produced by NADPH oxidases [18]. Activation of respiratory burst oxidase homolog D (RbohD) produces superoxide (O_2^-), which is converted to hydrogen peroxide (H_2O_2) by superoxide dismutase [19]. H_2O_2 accumulation can be measured with luminol-based detection methods to provide a quantitative evaluation of the PTI response. Early induced genes such as MAP kinases and WRKY transcription factors also provide a quantitative measure of PTI responses. Increased transcription of these genes can be detected within 15 minutes after PAMP application. Later PTI responses include callose deposition and the production of salicylic acid and ethylene [20].

The rice R-gene *Xa21* confers resistance to all tested isolates of *Xanthomonas oryzae* pv. *oryzae*, the rice blight pathogen. The corresponding Avr gene *Ax21* was found to be conserved not only in *X. oryzae* pv. *oryzae* but in *Xanthomonas* spp of soybean, tomato, pepper, citrus and *Brassica* plant species, and outside the genera in the plant bacteria *Xylella fastidiosa* [21]. *Ax21* therefore represents a conserved effector, not only within a species, but across bacterial pathogens. Although *Xa21* is not found in all rice genotypes it is now considered by some to be a PRR and *Ax21* a PAMP [22]. *Xa21* could potentially be used to confer resistance in other crop species where *Xanthomonas* spp are a pathogen of agronomic importance.

Other examples of cloned resistance genes that confer resistance to multiple pathogens include the tomato *Mi1* gene [23], which confers resistance towards root-knot nematodes, potato aphids, whitefly, viruses, bacteria and fungi, the lettuce gene *Dm3* [24], which confers resistance to downy mildew and lettuce root aphid, and the

1 tomato *Pto* gene, which when over-expressed confers resistance to the bacteria *P.*
2 *syringae* pv. *tomato* and *X. campestris* pv. *vesicatoria* and the fungus *Cladosporium*
3 *fulvum* [21, 25]. The multi-pathogen resistance conferred by these genes may also
4
5 have wider applications in resistance if incorporated into other crop species.
6
7
8
9

10 11 ETI and crop resistance

12 To achieve successful infection a pathogen must be able to manipulate the cellular
13 environment of the host plant, not only suppressing the plant's natural defence
14 responses, but also altering the cellular environment to allow it to grow and
15 reproduce. This is achieved by the production of an arsenal of proteins, collectively
16 known as effectors, which target plant defence pathways and metabolism [26]. The
17 rice blast fungus *M. oryzae* secretes Slp1, an effector protein that sequesters chitin
18 oligosaccharides to prevent their binding to CEBiP, thereby suppressing PTI in rice
19 [27]. The Pep1 effector from *Ustilago maydis*, the maize smut fungus, inhibits
20 peroxidase activity in maize, suppressing the oxidative burst [28]. Increasing numbers
21 of pathogen effectors are being identified. Understanding the role of these effectors
22 in suppressing the general PTI plant defence responses will enable us to develop
23 new approaches to disease resistance.

46 *X. oryzae* pv. *oryzae* produce Transcription Activator-Like Effectors (TALEs) that
47 bind to TALE-specific DNA sequences within the promoter regions of plant genes,
48 activating gene transcription to facilitate bacterial colonisation [29]. Rice resistance
49 genes effective against *X. oryzae* include R-genes which are constitutively
50 expressed, triggering ETI upon recognition of a pathogen *Avir* effector, but also R-
51 genes which are induced directly by the *Avir* protein. The recessive R-gene *xa13* is

believed to be an allelic variant of the rice gene *Os8N3*. *Os8N3* is transcriptionally activated by the TALE *PthXo1*, which is required for bacterial multiplication and disease development, but no transcript of *Os8N3* was detected in *xa13* genotypes of rice [30]. The recessive R-gene *xa5* is thought to interfere with the function of multiple TALEs. *Xa5* encodes for TFIIA γ , a component of the RNA II polymerase complex. Many TALEs may use this complex via interaction with TFIIA γ to activate transcription, and the *xa5* allelic variant prevents this interaction [29]. Genetic variants of the plant target genes of effectors could thus provide novel sources of resistance.

In a novel approach, TALEs have been used to create mutations within the promoter regions of target plant genes by fusing the DNA recognition repeats of native or customised TALEs with an endonuclease, creating TALE Nucleases (TALENs) [31,32]. TALENs were successfully used to generate site-specific DNA modifications in the promoters of plant TALE target genes, resulting in a modified promoter to which the TALE could no longer bind [33, 34]. The rice gene *OsSWEET14* encodes a member of the SWEET sucrose-efflux transporter family and is co-opted by the *X. oryzae* pv. *oryzae* effectors *AvrXa7* and *PthXo3* to divert sugars for the benefit of the bacteria [35]. Using tailor-made TALENs DNA sequence modifications, mainly small deletions, were generated in the *AvrXa7* and *PthXo3* binding sites of *OsSWEET14*. These modifications prevented the TALEs from activating transcription of the gene, while showing no apparent disruption of the normal function of *OsSWEET14* on rice development [36].

1 Whole-genome sequencing of plant pathogens has enabled bioinformatic
2 approaches to identify candidate effectors [37-39]. Small proteins with signal
3 peptides that would allow secretion of the protein into the plant are considered
4 potential effector candidates. In the oomycete pathogens *Phytophthora* spps., the
5 conserved sequences RXLR and CRN define families of effectors [40]. All *P.*
6
7 *infestans* Avr genes identified to date belong to the RXLR class of effectors. These
8 genes encode secreted proteins with a RXLR motif required for translocation into the
9 plant cell, followed by diverse and rapidly evolving C-terminal effector domains [41].
10 In *P. infestans* these families of effector protein are expanded 2-fold or more by the
11 insertion of transposable elements and other repetitive sequences compared to *P.*
12 *sojiae* and *P. ramorum* [37]. The dynamic nature of these regions of the pathogen's
13 genome may explain the great diversity of effectors and the rapidity with which *P.*
14 *infestans* overcomes resistance in potato.

31
32
33
34 Functional, *in planta* screening of candidate effectors would allow the identification of
35 matching Avir-R-gene interactions. In potato a rapid screening method for *P.*
36 *infestans* effectors was used to identify new R-genes in related *Solanum* spps [42].
37 R-genes that recognise highly-conserved, non-redundant effectors essential for
38 pathogenicity represent potentially durable sources of resistance [43].

48 Quantitative disease resistance and PTI in crops

49
50
51 R-genes commonly express dominant and clear resistant phenotypes and as such
52 were traditionally favoured by breeders for the ease by which they can be selected
53 within a breeding program. However race-specific R-genes are often effective for
54 only a short period of time, as virulence rapidly arises within the pathogen

population. In recent years crop breeders and researcher alike have shown a greater interest in sources of Durable Resistance, a term defined as “resistance that remains effective when deployed over extensive acreage and time in an environment favourable for the disease” [44, 45]. Although many of these sources of resistance have only partial effects, representing Quantitative Trait Loci (QTL), by combining these genes, crop varieties with acceptable levels of disease resistance can be obtained [46, 47].

Durable QTL include the wheat leaf rust resistance genes *Lr34* and *Lr46*. These loci, *Lr34/Yr18/Pm38* and *Lr46/Yr29/Pm39*, have also been shown to confer resistance to stripe rust and powdery mildew, and thus are examples of both race-nonspecific and multi-pathogen sources of resistance [48]. The *Lr34* gene encodes a protein resembling ABC transporters [49]. The rice *pi21* allele, which confers partial race-nonspecific resistance to the blast pathogen *M. oryzae*, is also considered durable [50]. Cloning of *pi21* identified a loss-of-function mutation in a gene encoding a proline-rich protein containing a heavy metal transport-detoxification domain and putative protein-protein interaction motifs. The wild-type gene *Pi21* appears to be required for *M. oryzae* infection; the mutant resistance allele *pi21* still allows but slows *M. oryzae* colonisation.

Work in several crop species suggests a relationship between disease resistance QTL and the defence responses triggered by PTI. Although further work is required to substantiate this, the association could provide new approaches to identifying and screening QTL in crop improvement programmes. In wheat, five quantitative trait loci (QTL) conferring multi-pathogen resistance to combinations of Septoria

1 tritici blotch, caused by *S. tritici*, Stagonospora glume blotch, caused by *S. nodorum*
2 and Fusarium head blight, caused by *F. graminearum* and *F. culmorum* have been
3
4 found in European wheat cultivars. These QTL may well represent genes conferring
5
6 general defence responses which are effective towards multiple pathogens.
7
8 Because these pathogens are genetically unrelated and infect different plant
9
10 tissues, the resistance mechanism may be triggered by widely-conserved pathogen
11
12 molecules similar to PAMPs [51].
13
14
15
16
17
18

19 In soybean correlations were observed between pathogen resistance against
20
21 *Pseudomonas syringae* and *Sclerotinia sclerotiorum* and the levels of PAMP-
22
23 triggered oxidative burst and defence gene induction. Four QTL were identified, one
24
25 related to total ROS production and three related to PAMP-induced gene
26
27 expression [52]. In maize, 29 QTL for resistance to Northern Leaf Blight
28
29 (*Setosphaeria turcica* (anamorph *Exserohilum turcicum*) have been reported [53].

32
33
34 Genome-wide nested association mapping identified multiple plant defence-related
35
36 genes associated with these QTL, including five RLK, consistent with their
37
38 involvement in PTI. Similar associations between RLK and QTL against Southern
39
40 leaf blight (*Cochliobolus heterostrophus*) have also been reported in maize [54].

44
45

46 Applications of quantitative disease resistance and PTI in crop improvement

47

48 Pyramiding QTL such *Lr34/Yr18/Pm38* and *Lr46/Yr29/Pm39* has proven effective
49
50 within the CIMMYT spring wheat breeding program [55]. However little is known
51
52 about how these different sources of resistance act together or what the best
53
54 combinations to achieve durable resistance are. Cloning of QTL genes will enable
55
56 the mechanisms behind each source of resistance to be determined, and allow

genes conferring different mechanisms of resistance to be combined to optimize durability. In rice QTL loci that co-localised with defence-related genes were pyramided by marker-assisted selection to develop rice cultivars resistant to *M. oryzae* (Box1). The similarities in sequence, gene organization and roles in disease resistance of germin-like protein (GLP) family members in rice and other cereals, including barley [56] and wheat [57], suggest that resistance contributed by the rice chromosome 8 OsGLP is a broad-spectrum, general mechanism conserved among the Gramineae [58].

With new knowledge about the PRRs, co-receptors and downstream events involved in PTI, the candidate gene approach could be used to identify new QTL genes for breeding. Genes identified in one crop could also be informative in related species. The barley homologue of the rice PRR gene CEBiP has been shown to have a role in basal resistance against *M. oryzae* [59], while EFR, found only in the Brassicaceae, when transformed into tomato conferred resistance to bacterial pathogens, including species of *Agrobacterium*, *Xanthomonas* and *Ralstonia* [60].

Application of cross species R-gene introduction in crop improvement

Many classical R-genes that mediate plant-pathogen ETI have now been cloned from several crop species [8]. These R-genes either recognise the pathogen through direct binding of the R-protein to the *Avr* pathogen effector, or indirectly through the interaction with another plant protein, the 'guardee', following its modification by the pathogen *Avr* effector (guard hypothesis). A well-studied example of a guardee protein is *RIN4* in *Arabidopsis*, which is required for resistance to *Pseudomonas syringe* pv. *tomato* mediated by the R-genes *RPM1* and *RPS2* [61,62].

1
2 The transfer of R-genes between sexually incompatible plant species using
3 transgenic technologies has been proposed as a means of achieving durable
4 pathogen resistance [63]. Such approaches allow different R-gene alleles to be
5 combined as R-gene stacks, presenting the pathogen with an extensive arsenal of
6 R-genes to evade if it is to circumvent recognition. Novel R-gene alleles, conferring
7 new recognition specificities can be generated by directed mutagenesis [64] or
8 domain swapping between R-genes [65]. Mutations generated within the potato R-
9 gene *Rx*, which confers resistance to the potato virus X (PVX), generated new
10 alleles effective against additional strains of the PVX virus, as well as a virus of the
11 tree species poplar, poplar mosaic virus [64].

22
23
24
25
26
27
28
29 The transfer of R-genes between species is however not without problems (Box 2).
30 Many R-genes effectively expressed in the donor species are lost in the recipient
31 owing to R-gene suppression [46,66]. Studies using the transgenic approach to
32 transfer R-genes have found that the R-gene triggered defence reactions in the
33 absence of a pathogen or specifically increased susceptibility to other pathogens
34 [63]. R-genes may require additional genes to function, such as R-gene guardees
35 that are not found in the recipient species [62].

49 Identification and exploitation of natural variation in disease resistance

50
51
52 The vast majority of resistance genes deployed in today's crop varieties were bred in
53 the traditional manner using resistance sources from the primary, secondary and to a
54 more limited extent the tertiary gene pool (Box 2). The almost bewildering array of
55 diversity present in these natural gene pools means that researchers targeting novel
56
57
58
59
60
61
62
63
64
65

1 resistances must deploy their finite resources carefully to maximise efficiency. The
2 Focused Identification of Germplasm Strategy (FIGS) is a method to rationally select
3 germplasm collection sites that are most likely to have produced selection pressure
4 for the trait in question [67]. In the search for disease resistance, factors taken into
5 account include the climatic conditions considered optimal for the development of the
6 disease in question, including minimum/maximum temperatures and relative
7 humidity, the geolocation of accessions previously demonstrated to contain
8 resistance, and ecological factors such as the natural range of pathogen secondary
9 host species. Although still in its infancy, FIGS has already been successfully used
10 to increase the efficiency of searches for novel resistances in wheat to stem rust [68]
11 and mildew [69].

30

31 Bi-parental mapping populations have been extensively used to genetically
32 characterise sources of disease resistance in many of our crops, and although
33 effective, they are limited by the genetic diversity that can be examined in each
34 population. Genome-Wide Association Screens (GWAS) offer a more global
35 approach, allowing the assessment of the genetic variability underlying a trait of
36 interest in a diverse genetic collection. Examples identified through GWAS include
37 lettuce spot blotch [70] and mildew [71] resistance, maize southern [72] and northern
38 leaf blight [73] resistance, as well as resistance to rust [74] and tan spot [75] in
39 wheat.

49
50
51

52 Although natural variation for disease resistance is extensive, our increasing
53 understanding of the genes involved in plant-pathogen interactions provides an
54 opportunity to utilise variation in target plant genes generated through mutation and
55
56
57
58
59
60
61

1 identified using TILLing procedures [76]. The classic example of mutation identifying
2 an agronomically valuable source of disease resistance is that of the powdery
3 mildew resistance gene in barley, *mlo*, which confers broad-spectrum resistance to
4 all isolates of the fungus *Blumeria graminis* f. sp. *hordei* (Box 3). More recently
5 several natural alleles of the barley transcription elongation factor *eIF4E*, which
6 confer bymovirus resistance, were identified in a collection of 1090 barley landraces
7 [77].

19 Concluding remarks

20
21 Research into plant-pathogen interactions for crop improvement currently falls into
22 two broad approaches. The first focuses on the identification of the pathogen factors,
23 PAMPs and effectors that are conserved across isolates and essential for pathogen
24 survival, and unable to withstand modification. The plant resistance genes which
25 recognise these conserved pathogen factors would theoretically have a greater
26 possibility of remaining effective over time because of the constraint on the pathogen
27 factor to evolve.
28
29
30
31
32
33
34
35
36
37
38
39
40

41 The second approaches the problem from the plant's perspective. Through the
42 identification and study of QTL for partial and often durable resistance, research is
43 showing that many of these QTL encode genes directly involved in resistance.
44 Expressing resistant alleles of these genes prevents the pathogen from exploiting its
45 host or activates general defence mechanisms used by the plant to restrict pathogen
46 growth. Often these genes have the added bonus of conferring resistance to multiple
47 pathogen species. Through the cloning of these QTL it is possible to determine the
48 mechanisms of resistance and thereby accumulate resistance genes with contrasting

1 and complementary mechanisms that can be used in conjunction to provide long-
2 term pathogen resistance.
3
4

5
6
7 These approaches are equally valid and complementary, with plant target genes of
8 pathogen effectors being identified as previously cloned resistance genes, and they
9 both work towards the same goal of breeding long-term, stable disease resistance
10 within nutritious and high-yielding crops that will feed the ever increasing human
11 population.

Figure Legends

Figure 1

Methods of studying PAMP-Triggered Immunity (PTI) in crops

A Production of reactive oxygen species (ROS) from leaf discs of Brassica cultivars after addition of PAMPs

ROS was measured with a luminometric assay expressed as Relative Light Units (RLU). The assay was performed in a 96-well microtitre plate with 8 replicate discs per cultivar. ROS measurement is a potentially high-throughput method, although the method needs to be optimised, and may not be suitable for all crop species.

B Induced relative gene expression in barley cultivars after addition of PAMP

Gene expression was measured 60 minutes after vacuum infiltration of the PAMP solution. Relative Expression (RE) of the PAMP responsive gene *HvCEBiP* (relative to barley Elongation Factor 1^α as control) after treatment with the PAMPs chitin and flg22. Not as high-throughput as method **A**, although can produce more consistent results. Selected genes need to be PAMP-responsive and up-regulated within 60 mins.

C Induced resistance against *Pseudomonas syringae* pv. *syringae* in wheat

PAMP solutions were syringe-infiltrated into leaves at the central zone (red) and the extent of the infiltration recorded (black ringed zone). After 24 h bacteria were

1 infiltrated into the central zone and Colony Forming units recorded after 3 days.
2 Induced resistance can be used to compare small numbers of cultivars (10-40) and
3 provides a direct readout of how PTI affects pathogen growth.
4
5
6
7
8
9

10
11 **D Callose formation observed 24h after syringe-infiltration of chitin into barley leaves**
12

13
14 Bright callose flecks were visible in the highlighted zone after staining with aniline
15 blue. Callose formation, lignin accumulation and metabolite changes are not
16 appropriate methods for high-throughput screening. They may be useful for
17 characterising PTI in selected varieties or mutants.

1
2 Glossary
3

4 **Avir:** Avirulence gene, the product of which, as defined by Flor's gene-for-gene
5 hypothesis, is recognised by a plant R-gene, activating ETI.
6
7

8
9 **CEBiP:** Chitin Elicitor Binding Protein. Plant PRR which binds the PAMP chitin.
10

11 **CERK1:** Receptor-Like Kinase required for CEBiP triggered PTI.
12

13 **DAMP:** Damage-Associated Molecular Pattern. Plant peptides or cell wall fragments
14 released during pathogen infection or wounding.
15
16

17 **EFR:** EF-Tu Receptor. Plant PRR which binds the PAMP EF-Tu.
18

19 **ETI:** Effector Triggered Immunity. Plant defence responses activated following the
20 recognition by the plant of pathogen effectors.
21
22

23 **FLS2:** Flagellin Sensing 2. Plant PRR which binds the PAMP flg22.
24

25 **GWAS:** Genome Wide Association Screen: The GWAS approach systematically
26 screens a genome-wide array of markers against the phenotypes of interest to
27 identify statistical associations between markers and phenotypes.
28
29

30 **PAMP:** Pathogen-Associated Molecular Pattern: Conserved pathogen molecules
31 recognised by the plant. Also known as Microbe-Associated Molecular Patterns
32 (MAMPs).
33
34

35 **PRR:** Pattern Recognition Receptor.
36

37 **PTI:** PAMP Triggered Immunity. Plant defence responses activated following the
38 recognition by the plant of PAMPs.
39
40

41 **QTL:** Quantitative Trait Locus. A genetic region which contributes to a phenotype
42 displaying a continuous distribution.
43
44

45 **R-gene:** Resistance gene.
46
47
48
49
50
51
52
53
54
55

1 **RLK:** Receptor-Like Kinase. Protein containing a receptor-recognition and a
2 functional kinase domain.
3

4 **TALE:** Transcription Activator-Like Effectors. TALEs bind to TALE-specific DNA
5 sequences within the promoter regions of plant genes activating gene transcription.
6
7

8 **TALEN:** Transcription Activator-Like Effector Nucleases. A fusion protein between
9 the plant gene DNA recognition repeats targeted by TAL effectors and the DNA
10 cleavage domains of FokI, a bacterial type IIS restriction endonuclease.

5 Informed resistance gene selection in breeding for disease resistance in rice
6

7
8
9 Analysis of crop varieties in germplasm breeding programs suggests that effective
10 and durable resistance would be best achieved by combining both quantitative trait
11 loci (QTL) and single resistance (*R*) genes into elite crop varieties [78]. The
12 incorporation of QTL for crop improvement however has not been widely adopted.
13
14 This is due in part to the lack of reliable markers for accumulation of the QTL, with
15 the genes that contribute to the quantitative trait being largely unknown. Determining
16 which genes confer the QTL phenotypes is complicated by the imprecision of QTL
17 mapping, and because the effects of each QTL are small and often vary with
18 environment. Recent approaches that build on knowledge of plant defence
19 responses show promise for targeted incorporation of resistance QTL for blast and
20 sheath blight into rice [79,80]. Convergent evidence, based on co-localization with a
21 disease resistance QTL, comparative sequence analysis, targeted gene expression
22 profiling, gene silencing studies, and functional analyses of gene family members,
23 has implicated several members of a germin-like protein (GLP) gene family in
24 contributing to a disease resistance QTL on rice chromosome 8 [81,82]. The QTL is
25 correlated with a polymorphism created by an insertion in the promoter of *OsGLP8-*
26 *6*, one of 12 GLP family members clustered on chromosome 8 [81]. The *OsGLP8-6*
27 promoter insertion adds *cis*-elements associated with early gene induction during
28 plant defence and after wounding, and the presence of the insertion is correlated
29 with higher induced expression of *OsGLP8-6* and increased resistance to both rice
30 blast and sheath blight diseases. In addition to the *OsGLP8* gene family, other
31 defence response genes have been shown to function in QTL-directed resistance

65

1 effective against a broad spectrum of diseases including bacterial blight, sheath
2 blight and rice blast [79].
3
4

5 Knowledge of variation in genes responsible for QTL function allows design of
6 molecular markers to facilitate accumulation of the QTL into elite germplasm [79,80].
7
8

9
10 However, because QTL alone might not suffice when disease pressure is high, in
11 practical breeding QTL should be used in combination with major R-genes. This
12 approach has been practiced with considerable success [78]. Rice lines that
13 exhibited high levels of resistance in multi-location trials were constructed by using
14 marker-assisted selection to combine QTL candidate genes and major blast R-genes
15 [79] (Figure 2). These lines have shown high levels of blast resistance after
16 continuous testing in disease hot spots in southern China for over 20 cropping
17 seasons (10 years)([82]; Liu Bin et al., unpublished data).

7 Resistance gene deployment from natural populations (primary, secondary and
8 tertiary gene pools)
9

10
11
12 Many sources of resistance have been introduced into our crops from external gene
13 pools. The primary gene pool consists of domesticated and wild specimens that are
14 completely interfertile. Although the relative absence of crossing barriers makes
15 deployment of genes from the primary genepool a matter of routine, it should be
16 recognised that moving a resistance gene from a wild accession into a commercial
17 breeding program requires much greater effort than simple reassortment of genes
18 already deployed in elite varieties. The introduction of resistance sources from
19 landrace or cultivated, but maladapted origin requires significant levels of effort on
20 the part of the breeder. The greater the burden of unadapted and undesirable traits
21 in the source of resistance, the more crossing and selection required to obtain a
22 high-yielding, resistant derivative adapted to the growing conditions of choice.
23
24
25
26
27
28
29
30
31
32
33
34
35
36
37
38
39

40 The use of related species (secondary genepool) as sources of resistance offers
41 several advantages, but equally several problems. The additional species can
42 encompass a wider range of genetic diversity which is accompanied by a
43 correspondingly deeper history of co-evolution with pathogens specific to the plant
44 taxa in question [83].
45
46
47
48
49
50
51
52

53 The tertiary genepool consists of species which have incompatible genomes, unable
54 of producing fertile F1 hybrids due to mismatched chromosome numbers/ploidy
55 levels and/or significant levels of non-homology etc. and which therefore require
56
57
58
59
60
61
62
63
64
65

1 radical interventions such as 'bridging crosses', chemically-induced chromosome
2 doubling and/or embryo rescue in order to introgress so-called 'alien' chromosome
3 segments into the background genotype of choice. Several such 'alien'
4 introgressions e.g., the replacement of the long arm of wheat chromosome 1B with
5 the short arm of rye (*Secale cereale*) chromosome 1R (known as the 1B/1R
6 translocation) in the 1920's, which brought resistance to leaf, stripe and stem rust
7 and to powdery mildew, as well as background-dependent alterations in biomass
8 and yield potential, is still maintained in a number of elite wheat varieties and
9 segregates rather like a single dominant locus in breeding programs. Against these
10 advantages most alien introgressions (1B/1R included) carry negative, as well as
11 positive traits, and due to the lack of homology with the recipient genomes,
12 homology-dependent recombination is largely unavailable to separate these negative
13 and positive traits over successive breeding cycles.

Box 3

1
2
3 Barley *mlo* resistance: broad-spectrum resistance for powdery mildew from natural
4
5 and induced sources.
6

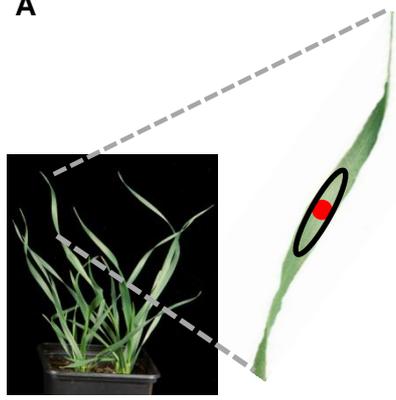

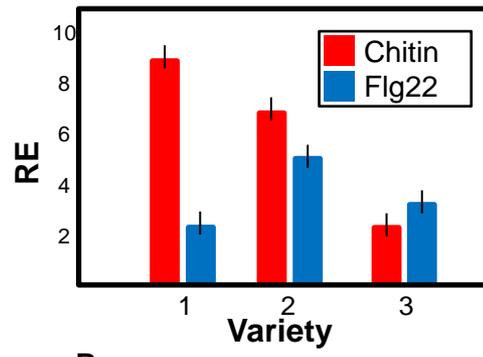

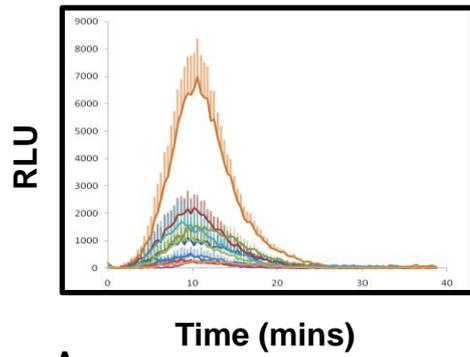

7
8
9 *Mlo* genes encode seven transmembrane domain proteins unique to and conserved
10 amongst land plants. The most studied is the *Mlo* gene of barley, *HvMlo*. The
11 HvMLO protein senses Ca^{2+} via an interaction with calmodulin and negatively
12 regulates cell death by inhibiting both actin-dependent, vesicle-associated as well as
13 actin-independent defence responses mounted as part of the basal defence reaction
14 [84]. Recessive loss-of-function *mlo* alleles have been shown to confer broad
15 spectrum resistance to a variety of appropriate and inappropriate powdery mildew
16 species in several crops. The barley *mlo* gene has conferred race-nonspecific
17 resistance to *Blumeria gaminis* f. sp. *hordei* for more than 30 years. The recessive
18 *er1* resistance gene of pea, effective against all races of pea powdery mildew for >50
19 years, is a naturally occurring allele of the *Mlo* homologue, as is the *or-1* gene in
20 tomato [85,86].

39 Evidence suggests that MLO function has been exploited as a susceptibility factor by
40 *Eryshiphales* (mildew) spp. for at least 200 million years [87]. As a route to broad-
41 spectrum powdery mildew resistance, MLO is a good target for mutagenesis in crops
42 where naturally occurring alleles do not exist. The tale of the barley *mlo* gene,
43 however, offers a cautionary note. Although a number of induced mutations in the
44 *Mlo* gene have been identified and characterised, none have been deployed in
45 barley breeding with the same success as the spontaneously occurring allele from
46 an Ethiopian landrace (*mlo-11*). *mlo-11*, which unlike induced mutants, came through
47 natural selection and minimized the documented negative yield penalty associated

1 with loss of *Mlo* function [88]. *mlo-11* was shown to possess partial *Mlo* function
2 through a complex rearrangement of the upstream regulatory sequences which,
3
4 though greatly reducing *Mlo* expression, still allow partial transcriptional read through
5
6
7 to an otherwise unaltered MLO protein [89].
